## Abstract

We present an in-depth analysis on the strength of the almost 10,000 passwords from users of an instant messaging server in Italy. We estimate the strength of those passwords, and compare the effectiveness of state-of-the-art attack methods such as dictionaries and Markov chain-based techniques.

We show that the strength of passwords chosen by users varies enormously, and that the cost of attacks based on password strength grows very quickly when the attacker wants to obtain a higher success percentage. In accordance with existing studies we observe that, in the absence of measures for enforcing password strength, weak passwords are common. On the other hand we discover that there will always be a subset of users with extremely strong passwords that are very unlikely to be broken.

The results of our study will help in evaluating the security of password-based authentication means, and they provide important insights for inspiring new and better proactive password checkers and password recovery tools.

## 1 Introduction

Even though much has been said about their weaknesses, passwords still are – and will be in the foreseeable future – ubiquitous in computer authentication systems. A peculiar characteristics of passwords is that they inherently carry a trade-off between usability and security: while strong passwords are hard for attackers to guess, they are on the other hand also difficult for the user to remember. As Richard Smith paradoxically notes, password best practices imply that “the password

must be impossible to remember and never written down” [17]. In light of this, it is not very surprising that users often knowingly choose to use weak passwords or circumvent security best practices, since they perceive that following them would get in the way of doing their work [1, 15].

To think sensibly about the security of systems that use passwords, it is therefore essential to analyze the characteristics of passwords chosen by users. In this work, we analyze a large dataset containing all user passwords from an instant messaging server located in Italy. Unlike previous empirical studies on passwords [10, 7, 18, 11, 3, 4, 9], this paper evaluates the strength of passwords against a variety of state of the art techniques for candidate generation. The analysis we conducted benefited from having access to the passwords in unencrypted form; this made it possible to measure the strength of all of them, including those that would hardly be cracked even by extremely powerful attackers.

We evaluate the strength of a password in terms of their associated search space size, that is the number of attempts that an attacker would need to correctly guess it. This measure does not depend on the particular nature of the authentication system nor on the attacker capabilities: it is only related to the attack technique and to the way users choose their password. The attack model and the characteristics of the system will instead define the cost that the attacker has to pay for each single guess. By combining this cost with our measures of password strength, it becomes possible to obtain a sound cost-benefit analysis for attacks based on password guessing on an authentication system.

As we will show, different attack techniques are advisable depending on the search space size that the attacker can afford to explore. This has to be

taken into account when proposing and evaluating new techniques for reducing the search space: they may be effective only if the strength of the attack falls within a given interval.

We show that password strength has an extremely wide variance: as a first approximation, the probability to guess a password at each attempt decreases roughly exponentially as the size of the explored search space grows. These diminishing returns imply that, in most cases, an attacker would eventually find a point where the cost of continuing the attack would not be justified by the probability of success. This study provides figures that can help designers and administrators in assessing the security of their systems by evaluating where that point resides.

## 2 Related Work

In this section we provide a short review of studies about password security, and make the case for the importance of measuring password strength. Attacks such as phishing or social engineering, where the user is misled in communicating the password to the attacker, are unrelated to password strength and therefore outside the scope of this work.

**Pricing Via Processing** To defend against intruders who repeatedly try password after password until they obtain access to the system, it is possible to limit the rate at which the attacker is allowed to try new passwords by requiring the user to perform an action with a moderate cost. While legitimate users would need to perform this action only once every time they try to log on, an attacker would need to repeat this process many times, resulting in a disproportionate cost that renders the attack worthless. The following measures belong to this category:

- CAPTCHAs [19], which require solving puzzles that are difficult without human intervention;
- key strengthening techniques, which require a few seconds of computation to derive a key from the passwords; this idea first appeared in the design of the UNIX system in the late '70s [10]. A modern key strengthening algorithm, where the computation length is config-

urable via the choice of a tunable parameter, is PBKDF2 [6].

It is important to note that these techniques impose a trade-off to legitimate users: if an honest user has to pay a cost  $c$ , the attacker must pay at most  $c \cdot s$ , where  $s$  is the strength of the password in terms of the number of attempts needed to guess it. The measures obtained in this paper can be used to estimate costs and benefits of these systems, and thus to properly tune this  $c$  parameter.

An alternative approach blocks accounts after a given number of failed attempts. This response, however, opens the door to denial of service attacks on user accounts and is ineffective unless the attack is specifically targeted towards a single user [13].

**Offline Attacks** In most cases, the authentication server does not store passwords in plain text. Instead, it keeps an “encrypted” version of them which is conceptually analogous to a hash: when a user attempts to log on, the password they provide is encrypted and compared to the stored value. In this way, even if an attacker obtains the encrypted passwords, these cannot be used right away to log on to the system. To make it costly for the attacker to guess the password by encrypting lots of password candidates, key strengthening techniques are again applied. Attacks based on pre-computing the encrypted version of the most likely passwords [11, 12] are defeated with the simple technique of “salting”, also known since the early days of UNIX: that technique works by appending a random number to the password before encrypting it, and then storing this number along with the encrypted password.

Since these techniques are based on the idea of making guessing attacks costly, the password strength that we are measuring is also a key parameter when evaluating the resilience of a password system to offline attacks.

**Password Recovery** We measure password strength by taking into account attempts to break them with state of the art techniques. The free password recovery software *John the Ripper*<sup>1</sup> identifies passwords by checking them against a large-sized dictionary, plus a fixed set of “mangling” rules,

<sup>1</sup><http://www.openwall.com/john/>

such as appending or prepending digits to dictionary words. According to Bruce Schneier’s description [16], AccessData’s proprietary Password Recovery Toolkit complements this approach with a “phonetic pattern” set generated via a Markov chain routine to generate meaningless but pronounceable passwords. In Section 5, we formalize a method based on the same idea and evaluate its merits in reducing the search space for cracking passwords.

**Proactive Password Checking** A proactive password checker is a system that forces (or advises) the user to choose complex enough passwords.

The impact of these checkers on actual password security is debatable: as Wu [20] notes, “[users are] very good at selecting passwords that are just ‘good enough’ to pass whatever checking is in place”. The MySpace social network requires users to have at least a non-alphabetic character in their password; in a set of leaked passwords, 86% of the users complied with this requirement by appending a number at the end of their password; for 20% of them that number was a “1” [14]. Furthermore, a proactive password checker could encourage users to use non-dictionary passwords that are related to their personal life such as dates, telephone numbers or license plate numbers [1]. For a motivated attacker, these passwords are even easier to guess than dictionary words. Moreover, a “strong password” in the abstract could force the user to write it down and leave it in a place where an attacker can easily find it. For example, many employees hide passwords under their mouse pads at their companies [17].

In general, it seems that password strength checkers actually increase system security only if they are seen by users as a tool that helps them and not just as an additional hoop they have to jump through to get their job done.

Existing password checkers are based on quite naive metrics [2, 21]: they check on password length, or resilience to “brute force” and dictionary based attacks; still, they do not take into account advanced cracking techniques. Our measure of strength as search space size can be used as the basis for more effective password checkers.

**Empirical Studies** It is a well known fact that many users almost invariably choose easy to guess passwords; current empirical studies, however, generally focus on a single kind of attack and neglect to quantify how strong the remaining share of passwords are with respect to more general attacks. To the best of our knowledge, no other work evaluates the strength of passwords over their whole strength spectrum and against all state-of-the-art techniques.

Analyses on dictionary attacks report a percentage of broken passwords varying between 17% and 24% [10, 7, 18]. In Section 4, before investigating the remaining stronger passwords, we obtain results of similar magnitude, varying with the type and size of dictionary used.

Some studies are based on a dataset of encrypted passwords, and only report on the ones that have been actually cracked [7, 11, 3, 9]; in comparison, we had access to the plain-text which gave us information on the passwords that would be computationally impractical to break.

In a 2007 study [4], Florencio and Herley obtained data about the passwords of about 500,000 users. That work provides interesting insights about user habits, but only quantifies password strength with a simple “bit strength” measure based on their length and on the use of uppercase, numeric, and non-alphanumeric characters; resilience against advanced password-cracking techniques is not taken into consideration.

### 3 Our Dataset

Our dataset contains the unencrypted passwords for the 9,317 registered users of an Italian instant messaging server. Storing passwords in plain text on the server is required by authentication algorithms such as CRAM-MD5<sup>2</sup>. User registration is free and no policy for password strength is enforced: even the empty password is allowed. The absence of strength enforcement allows us to investigate the behavior of users when choosing their password in the absence of external requirements.

Users are free to choose any unused username when registering. A total of 269 users (2.89% of the total) use the same string as both username and password. The single most effective attempt

<sup>2</sup><http://tools.ietf.org/html/rfc2195>

Figure 1: Password length distribution.

to guess a given user’s password would therefore be its own username.

Some users share the same password, and this results in 7,848 unique passwords. While in some cases this may be due to coincidences and use of too frequent passwords, other cases may be the consequence of the same people registering under different usernames at the same server.

The average password length is 7.86. Figure 1 shows the length distribution. Even though the full Unicode character set is usable for the passwords, only 124 different characters had been used. Frequencies of characters have very uneven distributions (see table 1): while one character out of 11 is an ‘a’, the most frequent uppercase character (‘A’) has a frequency of approximately 1 in 500.

In table 2, we show the matching ratio of various simple regular expression. More than 50% of the passwords contain only lowercase characters, and less than 7% contain non-alphanumeric characters. Around 15% of them consist of a string of lowercase characters followed by a numeric appendage.

We also analyzed a set of 33,671 leaked MySpace passwords [5, 14]. Since these passwords have been obtained through a phishing attack, they include those of less security-conscious users who fell for the attack. Moreover, MySpace requires users to insert non-alphabetic characters in their passwords, and this imposes an artificial impact on passwords that users, left alone, would choose. For these reasons, we consider this dataset less representative of actual user passwords than our primary one; we however use it in this work to corroborate some of our findings by validating them on another dataset.

| Character | Count  | Percentage |
|-----------|--------|------------|
| a         | 6,681  | 9.12%      |
| e         | 4,520  | 6.17%      |
| o         | 4,484  | 6.12%      |
| i         | 4,388  | 5.99%      |
| r         | 3,628  | 4.95%      |
| n         | 3,310  | 4.52%      |
| l         | 3,095  | 4.23%      |
| s         | 2,895  | 3.95%      |
| t         | 2,853  | 3.90%      |
| 1         | 2,518  | 3.44%      |

| b         | 1,624  | 2.22%      |
| 3         | 1,487  | 2.03%      |
| g         | 1,334  | 1.82%      |
| other     | 16,832 | 22.98%     |

Table 1: Character distribution.

| Expression      | Example | Matches |
|-----------------|---------|---------|
| [a-z]+          | abcdef  | 51.20%  |
| [A-Z]+          | ABCDEF  | 0.29%   |
| [A-Za-z]+       | AbCdEf  | 53.74%  |
| [0-9]+          | 123456  | 9.10%   |
| [a-zA-Z0-9]+    | A1b2C3  | 93.43%  |
| [a-z]+[0-9]+    | abc123  | 14.51%  |
| [a-zA-Z]+[0-9]+ | aBc123  | 16.30%  |
| [0-9]+[a-zA-Z]+ | 123aBc  | 1.80%   |
| [0-9]+[a-z]+    | 123abc  | 1.65%   |

Table 2: Percentage of passwords matching various regular expressions.

## 4 Dictionary Attack

Dictionary attack is the most effective technique to guess the weakest passwords. We evaluated password strength by using the dictionaries available in the already mentioned *John the Ripper* (JtR) password recovery tool. The extended dictionaries that we used are available for paid download from the program website<sup>3</sup>.

### 4.1 The Dictionaries

The JtR dictionaries contain words from 21 different human languages, plus a list of frequently used passwords. For some languages (like English and Italian), various dictionaries of different sizes are available: the smaller ones contain only the most frequently used words while the bigger ones also contain more obscure words, the rationale being that more common words are more likely to be chosen as passwords. Taken together, all dictionaries account for almost 4 million words. A bigger dictionary containing more than 40 millions words is obtained using “mangling” rules that attempt to create more complex passwords by altering dictionary words, for example by juxtaposition of dictionary words or by appending a number at the end of the word.

An often-advised technique to create strong but easy to remember passwords is to turn phrases into passwords by extracting an acronym, possibly also using punctuation. For example, the phrase “Alas, poor Yorick! I knew him, Horatio” becomes “A,pY!Ikh,H”. We also evaluated such acronyms with a dictionary created by Kuo et al. [8] that was put together by scraping websites displaying memorable phrases, such as citations and music lyrics.

### 4.2 Experimental Results

We simulated dictionary attacks with all the JtR dictionaries. Table 3 shows the results for the most representative instances.

The “found” column lists the percentage of passwords that appear in that dictionary; the “guess probability” column reflects the probability that a random word from that dictionary matches a random password: a rational attacker would try a word from that dictionary only if the benefit of cracking

| Dictionary           | Size       | Found  | Guess prob.          |
|----------------------|------------|--------|----------------------|
| Frequent passwords   | 3,114      | 7.25%  | $2.33 \cdot 10^{-5}$ |
| English 1 lc         | 27,424     | 4.91%  | $1.79 \cdot 10^{-6}$ |
| English 2 lc         | 296,809    | 9.42%  | $3.17 \cdot 10^{-7}$ |
| English 3 lc         | 390,532    | 11.59% | $2.97 \cdot 10^{-7}$ |
| English extra lc     | 444,678    | 8.03%  | $1.81 \cdot 10^{-7}$ |
| Italian 1 lc         | 63,041     | 3.71%  | $5.89 \cdot 10^{-7}$ |
| Italian 2 lc         | 344,074    | 14.89% | $4.33 \cdot 10^{-7}$ |
| All above            | 1,117,767  | 25.51% | $2.28 \cdot 10^{-7}$ |
| All JtR dictionaries | 3,917,193  | 25.94% | $6.62 \cdot 10^{-8}$ |
| All JtR + mangling   | 40,532,676 | 30.12% | $7.43 \cdot 10^{-9}$ |
| Mnemonics [8]        | 406,430    | 1.27%  | $3.12 \cdot 10^{-8}$ |

Table 3: Dictionary attacks. The “lc” acronym stands for all-lowercase dictionaries: those containing uppercase letters are matched by very few words in our dataset. The English 1, English 2 and English 3 dictionaries, like Italian 1 and Italian 2, are listed in growing size; each word belonging to a smaller dictionary is also contained in the bigger versions.

the password exceeds the inverse of that probability times the cost of the effort for trying that password.

The “English extra” dictionary has a slightly misleading name: it contains words that don’t appear in a regular dictionary but that users are likely to use, such as proper nouns, common misspellings or alterations of words. Many of them are language-agnostic (e.g., “Aldebaran”) or come from non-English languages (“Mariela”).

As the server is in Italy, most users are Italian. The amount of English words found in passwords is not particularly surprising for those who know the tendency that natives have towards the heavy use (and abuse) of English. An interesting feature is the noticeably higher density of common English words (those present in the small “English 1” dictionary); that phenomenon is much less relevant with respect to Italian. We think that this is caused by the fact that most users know English as a second language, and thus are less inclined to use an obscure word as their password. This suggests that it might be good practice to use one’s native language to create stronger passwords.

The most important lesson drawn from this data is the principle of *diminishing returns*: the probability of guessing a word sharply decreases as the dictionary grows. The 3,100-word dictionary of fre-

<sup>3</sup><http://www.openwall.com/wordlists/>

quent passwords cracks 7% of those in our datasets; by increasing roughly 300 times the size of the dictionary up to more than one million and including all Italian and English words, the number of cracked passwords rises to 25%. When the number of attempts grows beyond 40 millions by including other languages and mangling, only 5% more of the passwords are found. To put it in another way, the probability of guessing a given password by trying an element of the “frequent passwords” dictionary is one in 43,000. On the other hand, after having tried all the frequent passwords and the Italian and English dictionary, the probability of guessing by using another dictionary word is less than one in 500 million! Since the guessing probability decreases so sharply, it is conceivable that in many cases it won’t be worth trying a bigger dictionary for the attacker.

We also observe that the mnemonic dictionary is quite ineffective. This may be due to several reasons: first, few users actually use mnemonics for their passwords; second, they are actually much harder to break with dictionary attacks. Moreover, we are not able to ascertain whether the habit of choosing English passwords for Italian users would carry over to the use of mnemonics. Our data is, at the moment, insufficient to point towards one reason or the other.

## 5 Markov Chain-Based Attack

The fact that dictionaries fall short does not mean that an attacker would need to resort to an exhaustive brute-force attack: some passwords are much more likely to be chosen than others. As seen in Section 3, there is a very uneven distribution of character choice. Moreover, other regularities exist: passwords are usually made of pronounceable sub-strings and/or sequences of keys that are close on the keyboard.

In this section, we describe and validate an attack based on Markov chain-based modeling of the frequencies of sub-strings with parametric length  $k$ , or  $k$ -graphs. This allows us to label candidate passwords with variable probabilities, where strings that are labeled as more likely are checked first. Some password generating utilities actually use this kind of modeling to obtain meaningless but pronounceable passwords on the grounds that they’re

easier to remember, thus sacrificing some strength for usability<sup>4</sup>.

### 5.1 The Technique

We base our formalization on the techniques shown in [11], extending the model so that it applies to sub-strings of length 3 and more. This model represents a password choice as a sequence of random events: first, the length of the password is chosen according to a given probability distribution; then, each character of the string gets extracted according to a conditional probability depending on the previous  $k - 1$  characters.

We encode the characteristics of passwords via two functions,  $\lambda$  and  $\nu$ .  $\lambda$  represents the length distribution of passwords so that, for example,  $\lambda(8)$  is the probability that the password has length 8.  $\nu$ , instead, represents the conditional probability of each  $k$ -graph with respect to the corresponding  $(k - 1)$ -graph:  $\nu(c_1 \dots c_k | c_1 \dots c_{k-1})$  is the probability that the character  $c_k$  follows the sub-string  $c_1 \dots c_{k-1}$ . For  $k = 1$ ,  $\nu(c)$  expresses the frequency of  $c$ , that is, the probability that a random character in a password coincides with  $c$ .

By choosing  $k = 1$ , thus focusing on character frequency, the probability  $P_1(\alpha)$  that our model will generate a string  $\alpha$  (where its length is  $|\alpha|$  and its  $i$ th character is  $\alpha_i$ ) is

$$P_1(\alpha) = \lambda(|\alpha|) \prod_{1 \leq i \leq |\alpha|} \nu(\alpha_i).$$

To derive  $P_k$  with  $k \geq 2$ , we will adopt the convention that  $\alpha_i = \perp$  whenever  $i \leq 0$ , where “ $\perp$ ” is a special character not allowed to appear in passwords. For example, we write the probability that a password starts with the “a” character as  $\nu(\perp \perp \text{a} | \perp \perp)$ ; the probability that a “b” follows an initial “a” is instead  $\nu(\perp \text{ab} | \perp \text{a})$ . Given this, we can formalize the digraph-based probability  $P_2$  as

$$P_2(\alpha) = \lambda(|\alpha|) \prod_{1 \leq i \leq |\alpha|} \nu(\alpha_{i-1} \alpha_i | \alpha_{i-1})$$

and, in general,

<sup>4</sup>See for example `gpw` (<http://www.multicians.org/thvv/tvvtools.html#gpw>), `apg` (<http://www.adel.nursat.kz/apg/>), `otp` (<http://www.fourmilab.ch/onetime/>).

$$P_k(\alpha) = \lambda(|\alpha|) \prod_{1 \leq i \leq |\alpha|} \nu(\alpha_{i-k+1} \dots \alpha_i | \alpha_{i-k+1} \dots \alpha_{i-1})$$

### 5.1.1 Estimating $\nu$ and $\lambda$

It is obviously important that the probabilities encoded in the  $\lambda$  and  $\nu$  functions are representative of the real characteristics of passwords. We do this by adopting a set of strings as a training set and setting  $\lambda(x)$  as the fraction of strings of length  $x$ . Denoting  $C$  as the character set and  $\sigma(c_1 \dots c_k)$  as the number of occurrences of the sub-string  $c_1 \dots c_k$  in the whole training set, we set

$$\nu(c_1 \dots c_k | c_1 \dots c_{k-1}) = \frac{\sigma(c_1 \dots c_k)}{\sum_{\bar{c} \in C} \sigma(c_1 \dots c_{k-1} \bar{c})}.$$

In the absence of a representative training set of passwords, a dictionary can be used as in [11]. As we will experimentally show in Section 5.2, using passwords themselves as training set finally results in a better model. In this case, when computing  $P_k(\alpha)$  in our experiments,  $\alpha$  itself must be removed from the training set and should not be taken into account when computing the values of  $\lambda$  and  $\sigma$ .

As mentioned in Section 3, some users share the same password. This might be due to chance and to the fact that those passwords are quite trivial; another possibility is that they come from the same user registering many accounts and using the same passwords for all of them. In the latter case, an attacker would not have access to the password in a representative training set, and it would be correct for our purposes to remove all copies of the password from the training set. Since we cannot discriminate between the two cases, we will adopt a conservative approach that may result in overestimating the capabilities of the attacker, therefore discarding only a single copy of the password from the training set.

A model with higher values of  $k$  should be more accurate, but the process of creating it is more difficult and expensive. In the extreme, a model with  $k$  exceeding the maximum password length would explicitly list the probability of occurrence of each possible password: this would require prohibitive training set size and storage capabilities (the required space is of the order of  $|C|^k$ , where  $|C|$  is the size of the character set). With limited resources,

---

**Algorithm 1** Explicit counting of search space size.

---

```

function SIZE( $c_1 \dots c_{k-1}, l, t$ )
     $\triangleright c_1 \dots c_{k-1}$ : state,  $l$ : string length,  $t$ :
    threshold
    if  $l = 0$  then return 1
     $s \leftarrow 0$ 
    for all  $\bar{c} \in C$  do
         $p \leftarrow \nu(c_1 \dots c_{k-1} \bar{c} | c_1 \dots c_{k-1})$ 
        if  $p \geq t$  then
             $s \leftarrow s + \text{SIZE}(c_2 \dots c_{k-1} \bar{c}, l - 1, t \cdot p)$ 
    return  $s$ 

function TOTAL_SIZE( $t$ )
     $\triangleright t$ : threshold
    return  $\sum_i \text{SIZE}(\perp \dots \perp, i, t \cdot \lambda(i))$ 

```

---

when a  $k$ -graph does not appear in the training set due to under-sampling, then the probability of a password containing that  $k$ -graph is computed as 0. Such a model would therefore never generate the required password.

### 5.1.2 Computing The Search Space Size

So far, we have described a model that assigns probabilities to passwords, with the aim of measuring how likely it is that a user would actually select a given password. A rational attacker would use this model by enumerating candidate passwords starting with the most likely ones and continuing in decreasing order of probability.

In order to measure the search space size that such a strategy would need to explore before finding a given password, we have to find out how many unsuccessful candidates would be generated before the correct one: if the Markovian model labels the probability of a password as  $p$ , its associated search space size would therefore be the number of strings with probability of occurrence higher than or equal to  $p$ .

**Explicit Counting** The most obvious system for computing the search space size up to a given threshold is to plainly enumerate it. In Algorithm 1, we show how this can be implemented with a simple recursive algorithm.

---

**Algorithm 2** Approximation of search space size.

---

```

function APPR_SIZE( $c_1 \dots c_{k-1}, l, t$ )
    ▷  $c_1 \dots c_{k-1}$ : state,  $l$ : string length,  $t$ :
    log-threshold
    if  $l = 0$  then return 1
     $s \leftarrow 0$ 
    for all  $\bar{c} \in C$  do
         $\bar{t} \leftarrow t - \lceil -\log_b \nu(c_1 \dots c_{k-1} \bar{c} | c_1 \dots c_{k-1}) \rceil$ 
        if  $\bar{t} \geq 0$  then
             $s \leftarrow s + \text{CACHE\_SIZE}(c_2 \dots c_{k-1} \bar{c}, l - 1, \bar{t})$ 
    return  $s$ 

function CACHE_SIZE( $c_1 \dots c_{k-1}, l, t$ )
    ▷ We store results from approx_size in a
    cache  $K$ 
    if  $(c_1 \dots c_{k-1}, l, t) \notin K$  then

---

**Approximate Estimation** As the search space grows, the above approach becomes extremely expensive and should be replaced with an approximate estimation method [11]. By fixing a base  $b > 1$ , any probability  $p$  can be approximate as  $b^{-l}$  for an integer value  $l \geq 0$ . Choosing  $l = \lfloor -\log_b p \rfloor$  approximates  $p$  by excess, while  $l = \lceil -\log_b p \rceil$  approximates by defect. To help intuition,  $l$  can be seen as a discrete “password strength” value, which can be computed as the sum of strengths for each  $k$ -graph contained in the password. Values of  $b$  closer to 1 result in a finer granularity for our approximation, at the cost of an increase in computation.

By adopting such an alteration, the computation gets a big speedup by memoizing the parameters and results of each APPR\_SIZE call, and returning them when the function is called again with the same parameters. This couldn’t be done with the former version, since the  $t$  threshold parameter of the SIZE function is a floating point number which is very likely to be different at each function call.

Since we are aiming for a conservative estimate for the search space that approximates by excess the capabilities of the attacker, we use approxima-

Figure 2: Search space size versus probability threshold for the  $k$ -graph Markovian model. The plotted curves show the result of the exact computation of Algorithm 1, while the points marked by crosses are the result of the approximation of Algorithm 2.

tion to obtain a lower limit for the search space size. To do this, we approximate the starting threshold by defect and all the  $\nu$  probabilities by excess.

The result of these modifications is the approximate function defined in Algorithm 2.

## 5.2 Experimental results

This section describes the results of the experiments described above when applied to our password dataset. Unless otherwise specified, we use the passwords themselves as training set.

**Search Space Size Versus Probability Threshold** In Figure 2 we show the size of search space containing strings labeled with a probability greater or equal to a given probability threshold. This is computed for different values of  $k$  and using both the exact count and the approximate measure from Algorithm 2. We used a parameter  $b = 1.01$ ; with that choice, we obtained a relative error of the order of 5% (not noticeable in the figure due to the log-log scale).

By choosing  $1 \leq k \leq 3$  (i.e., basing the model on sub-strings of lengths 1 to 3), the probabilities of strings generated by the model roughly follow a

Figure 3: Search space size versus fraction of guessed passwords.

Figure 4: Search space size versus fraction of guessed passwords on the MySpace dataset.

power law. It is interesting to note that this mirrors frequencies of words in human natural languages, which obey the power law as well [22]. For  $k \geq 4$ , the number of candidate strings grows definitely slower as the probability threshold increases; this is due to the fact that each  $k$ -graph is represented by a low number of strings in the training set, and the number of strings that can be obtained by combining  $k$ -graphs that are present in the dataset is limited. We conjecture that, with a bigger training set, we would obtain a power-law distribution also in this case.

In the following, we use the approximate approach to estimate the search space size where the exact value becomes either impractical or impossible to compute. We compute data points for each  $p = 10^{-i}$  threshold ( $i$  being an integer) and interpolate with the power law that connects the points (a straight line in the log-log plot).

**Password Strength** In Figure 3, we plot the fraction of passwords guessed as a function of the search space size.

With higher values of  $k$ , we obtain better results for the weaker passwords due to the more precise modeling obtained in this case. However, the passwords that include  $k$ -graphs not represented in the training set cannot be guessed. Methods based on smaller  $k$  values become more effective because they can “generalize” some more. In practice, the opti-

mal strategy depends on the resources of the attacker, measured by the number of attempts that can be tried.

The “diminishing returns” effect that we discovered for dictionary attacks also applies to this technique: even when choosing the best value of  $k$  for each case, around 100,000 candidates need to be tried in order to guess 20% of the passwords ( $k = 5$ ); this number rises to roughly 1.1 billions candidates for a success rate of 40% ( $k = 3$ ); the search space needed to break 90% of the passwords grows to approximately  $3 \cdot 10^{17}$  ( $k = 2$ ). With such a huge variance in the size of the search space, it seems that no reasonable attack based on password guessing would succeed in guessing all passwords – excepting those cases where users are artificially forced to limit password strength, for example by imposing a maximum length.

**MySpace Passwords** In Figure 4, we repeat our measurements using MySpace passwords in the place of our main dataset both as training set and as guessed passwords. We obtain qualitatively similar results – in particular, higher values of  $k$  are more appropriate as training sets for weaker passwords, and the diminishing returns principle holds. From a quantitative point of view, the search space for weak password is bigger, while it is smaller for stronger passwords. We think that this is mainly due to the particularities of the dataset: weak pass-

Figure 5: Comparison of brute force and Markov-model based attacks.

words are made stronger by the requirement of non-alphabetic characters; strong passwords created by security-conscious users, on the other hand, are under-represented since such users are not likely to fall victim to a phishing attack.

**Brute Force** In Figure 5, we compare the brute force approach with our Markovian modeling. The brute force approach starts by trying the empty password, then proceeds with enumerating all possible passwords with increasing length. The full Unicode character set currently has more than 99,000 characters<sup>5</sup>, but many of them are very rare and definitely unlikely in a password; to account for this, we again took a conservative approach over-estimating the attacker capabilities, and took into account only the 124 characters that we have found in our dataset.

In all but the most extreme cases, the Markovian model proves more efficient by orders of magnitude. It is not before  $10^{40}$  candidates (and having found 99.7% of the passwords) that a brute force approach becomes more effective than the Markovian model with  $k = 1$  (character frequencies). This number is well beyond the capabilities of any realistic attacker: to put this in context, a cluster of a thousand 10 GHz machines would need more than  $3 \cdot 10^{19}$  years to reach that number of iterations, even assuming that they are able to try a password

<sup>5</sup><http://www.unicode.org/press/pr-ucd5.0.html>

Figure 6: Scatter plots of password length (Y axis) versus strength (associated search space size on X axis).

for each clock cycle.

**Strength and Password Length** In Figure 6, we highlight the relationship between a password length and its strength. As the graphs show, the assumption that longer passwords are stronger can only be regarded as a rule of thumb: a short password containing infrequent characters and/or sequences thereof can be actually stronger than a noticeably longer one. The correlation between length and strength becomes weaker as the  $k$  parameter grows: long but weak passwords may be based on predictable long patterns that are less efficiently predicted by models based on lower  $k$  values. For example, it is quite likely that the “abcd” sequence is followed by a “e”; a model based on digraphs, though, cannot capture this and can only model which character is more likely to follow a “d”.

**Training Sets** Figure 7 illustrates how the choice of training sets affects the attack performance. The training sets used are our sets of usernames and passwords, the MySpace leaked passwords, the JtR common password dictionary, and Italian and English dictionaries.

The most effective training set is the real password set. The “common passwords” dictionary from JtR is more representative of real passwords

Figure 7: Comparison of various training sets for guessing passwords in our dataset ( $k = 2$ ).

Figure 8: Comparison of complexity between passwords and usernames.

than standard dictionaries, since it contains combinations of characters, such as punctuation and digits, that don’t appear in standard dictionaries. Still, it appears that “average” passwords do not closely resemble the most common ones.

The case of MySpace passwords as training set is interesting: they are close to the performance of our password dataset for strong passwords, but they do not represent weak ones well. We believe this is due to the over-representation of non-alphabetic characters, which are required to be present in MySpace passwords. The difference in coverage on strong passwords (around 5% with equivalent search space size) can also be attributed to this feature, as well as to the following factors:

- Difference in computer literacy: the MySpace sample contains only the victims of a phishing attack;
- Difference in language: MySpace users are distributed worldwide.

If a representative training set of real passwords is not available to the attacker, usernames are by far the most effective training set. It appears that, when users are asked to provide a username and a password, they employ similar criteria. This is quite surprising since the two strings need to satisfy very different, and arguably conflicting, criteria: good usernames are easily memorable, while a

strong password has to be as difficult to guess as possible.

**Usernames** The former result suggests a consideration: usernames and passwords are chosen simultaneously, when registering a new account. A user wants both strings to be memorable, since the two are needed in order to log on successfully. However, while there is no incentive in choosing complex usernames, a security conscious user will commit some effort to make his password more complex.

The difference in complexity between usernames and passwords is therefore a way to measure the effort that users willingly put in making their passwords more complex: while usernames can be very long or difficult to guess, this is not likely to happen as the result of a conscious attempt to do so.

In Figure 8, we compare the search space size associated to usernames and passwords. Matching what we have done with passwords, the training set used to guess a given username consists of all the usernames except the one under scrutiny. It turns out that the effort that users put in creating complex passwords is measurable, but it is overall quite weak: given a choice for  $k$  and a search space size, the percentage of “cracked” usernames never exceeds the cracked passwords by more than 15%.

## 6 Combined Strategy

Our results confirm that no single strategy or technique is more effective in reducing the search space: dictionaries are most effective in discovering the weakest passwords; the coverage (fraction of passwords that are in the dictionary) grows as the dictionary size grows, but this entails a loss in precision (fraction of dictionary items that are actual passwords). The Markov-chain based technique should be used when dictionaries are exhausted. Higher values of  $k$  obtain better results at first, but after a number of attempts they become quite ineffective.

No single strategy is the best one for all cases; this, in fact, validates the approach taken by password recovery systems that adopt bigger and bigger dictionaries in cascade, and resort afterwards to Markov-based techniques. In this section, we summarize our results by presenting the results that an attacker would be able to obtain by using such a technique.

Consistently with our approach of estimating the capabilities of the attacker by excess in the face of uncertainty, we assume that the attacker has access to a password training set which is as effective as the one we obtain from the clear text. Furthermore, we also assume that the attacker is able to predict the effectiveness of techniques that we measured in Sections 4 and 5.

Based on this knowledge, using the training set as a dictionary, the strategy for the dictionary-based first part of the attack is as follows:

1. Try the username;
2. Try the common passwords dictionary;
3. Try all passwords in the training set;
4. Try the English 1 dictionary;
5. Try the Italian 1 and 2 dictionaries;
6. Try the English 2, 3 and extra dictionaries;
7. Try all remaining JtR dictionaries;
8. Try mangling rules.

If this approach is not sufficient, one should resort to the Markovian model.

Figure 9: Search space size for passwords that are not found in any dictionary. In the inner frame, detail on the first iterations.

In Figure 9, we show the search space for the passwords that have not been discovered within any dictionary. With respect to figure 3, there is a sharp decrease in the success rate until the search space size reaches approximately  $10^8$ . In particular, techniques with  $k = 5$  and  $k = 4$  are unsuccessful to break more than, respectively, roughly 1% and 4% of the passwords. This matches with the intuition that dictionary-based attacks are more useful against the less complex passwords.

Based on the data represented in Figure 9, an efficient strategy for the attack would be as follows:

1. Try 500,000 candidates with the model based on  $k = 5$ ;
2. Try 7,000,000 candidates with  $k = 4$ ;
3. Try 700,000,000 candidates with  $k = 3$ ;
4. Try  $7 \cdot 10^{16}$  candidates with  $k = 2$ ;
5. Continue with  $k = 1$ .

In Table 4, we summarize the search space size and percentage of cracked passwords for each of these steps. This is the answer to our original question: how many attempts an attacker would need in order to guess a given percentage of the passwords. By integrating this with system-specific knowledge such as the computational cost needed to perform a single guess and the amount of resources that the

attacker has access to, it is possible to estimate the percentage of passwords that are vulnerable to a given attack.

## 7 Conclusion

As the bibliography of this work witnesses, the first studies on password cracking date back to almost 30 years ago. Still, the techniques that are used in state of the art password-cracking applications are quite simple: decades of research suggest that it is possible to do better than applying simple Markov chain-based modeling techniques.

The results of our measurement study may provide an explanation as to why not much has been done in this direction: the diminishing returns effect implies that, even if the size of the search space decreases by orders of magnitude, the percentage of passwords that an attacker would be able to crack in a given number of attempt would increase only by a non-impressive percentage. In addition, it is likely that an innovative strategy for exploring the search space would improve over the state of the art only for a given interval of search space sizes; the low-cost/high-reward part of the search space is already easily covered by dictionaries of frequent passwords. When such an attack proves ineffective, an attacker could change target to find an easier prey, or use other means of attack which are not based on the password strength, such as social engineering, phishing, or exploitation of vulnerabilities in software or in the protocol: as the energies instilled into an unsuccessful attack grow, the attack is more and more likely to be unsuccessful in the future as well.

We focused on the strength of passwords chosen by users in the absence of password strength enforcement. As pointed out in Section 2, it is debatable that systems enforcing password complexity actually increase security: they may instead lead users to circumvent the enforcement techniques by adopting insecure behavior. To assess this, measuring password complexity with and without enforcement should be coupled with an analysis of user behavior.

Another interesting question yet to be addressed regards the correlation between password strength and the domain they are related to. In particular, how will the password strength of a user vary

| Step                   | #attempts              | Cracked |
|------------------------|------------------------|---------|
| Username               | 1                      | 2.88%   |
| Common passwords       | 3,115                  | 9.95%   |
| Training set           | 10,431                 | 28.83%  |
| English 1              | 36,574                 | 30.51%  |
| Italian 1              | 98,511                 | 32.25%  |
| Italian 2              | 373,834                | 36.31%  |
| English 2              | 632,613                | 37.18%  |
| English 3              | 722,215                | 37.69%  |
| English extra          | 1,123,841              | 40.07%  |
| JtR - all dictionaries | 3,923,660              | 41.14%  |
| Mangling               | 40,538,747             | 44.26%  |
| Markov chain - $k = 5$ | 41,070,093             | 45.05%  |
| Markov chain - $k = 4$ | 48,051,199             | 46.76%  |
| Markov chain - $k = 3$ | $\sim 750,000,000$     | 58.10%  |
| Markov chain - $k = 2$ | $\sim 7 \cdot 10^{16}$ | 91.06%  |
| Markov chain - $k = 1$ | $\sim 10^{40}$         | 99.71%  |

Table 4: Cumulative number of attempts and of guessed passwords for the multi-step approach. Candidates that would be checked in more than one dictionary are counted only once. For the Markov chain technique with  $k \leq 3$ , the search space has not been generated explicitly and its size has been approximated with Algorithm 2.

if getting an account compromised would result in a noticeable loss? In [4], some evidence that users actually choose better passwords for accounts related to valuable assets (e.g., PayPal) is reported. Unfortunately, the bit-strength measure adopted is quite simple. Further investigations would be required to obtain actual figures in terms of attacker costs in order to break an account.

## 8 Acknowledgements

The authors would like to thank Sebastian Porst and Roger Grimes for having shared the set of MySpace passwords, and Cynthia Kuo, Sasha Romanosky, and Lorrie F. Cranor for having shared their mnemonics dictionary.
